ABSTRACT

BACKGROUND
The management of metastatic breast cancer requires monitoring of the tumor burden to determine the response to treatment, and improved biomarkers are needed. Biomarkers such as cancer antigen 15-3 (CA 15-3) and circulating tumor cells have been widely studied. However, circulating cell-free DNA carrying tumor-specific alterations (circulating tumor DNA) has not been extensively investigated or compared with other circulating biomarkers in breast cancer.

METHODS
We compared the radiographic imaging of tumors with the assay of circulating tumor DNA, CA 15-3, and circulating tumor cells in 30 women with metastatic breast cancer who were receiving systemic therapy. We used targeted or whole-genome sequencing to identify somatic genomic alterations and designed personalized assays to quantify circulating tumor DNA in serially collected plasma specimens. CA 15-3 levels and numbers of circulating tumor cells were measured at identical time points.

RESULTS
Circulating tumor DNA was successfully detected in 29 of the 30 women (97%) in whom somatic genomic alterations were identified; CA 15-3 and circulating tumor cells were detected in 21 of 27 women (78%) and 26 of 30 women (87%), respectively. Circulating tumor DNA levels showed a greater dynamic range, and greater correlation with changes in tumor burden, than did CA 15-3 or circulating tumor cells. Among the measures tested, circulating tumor DNA provided the earliest measure of treatment response in 10 of 19 women (53%).

CONCLUSIONS
This proof-of-concept analysis showed that circulating tumor DNA is an informative, inherently specific, and highly sensitive biomarker of metastatic breast cancer. (Funded by Cancer Research UK and others.)
Breast cancer is the most common cancer and the leading cause of cancer-related death in women worldwide.\textsuperscript{1} Metastatic breast cancer remains an incurable disease but is treatable by means of serial administration of endocrine, cytotoxic, or biologic therapies. The monitoring of treatment response is essential to avoid continuing ineffective therapies, to prevent unnecessary side effects, and to determine the benefit of new therapeutics. Treatment response is generally assessed with the use of serial imaging, but radiographic measurements often fail to detect changes in tumor burden. Therefore, there is an urgent need for biomarkers that measure tumor burden with high sensitivity and specificity.

Cancer antigen 15-3 (CA 15-3) is a serum biomarker that is clinically useful in some patients with metastatic breast cancer but has a sensitivity of only 60 to 70\textsuperscript{.2-4} The enumeration of circulating tumor cells has emerged as a promising biomarker. Although there are numerous methods to detect circulating tumor cells in the research setting,\textsuperscript{5-7} the CellSearch System is the only test approved by the Food and Drug Administration. The system has a sensitivity of approximately 65\% for detecting circulating tumor cells (≥1 cell per 7.5 ml of blood) in patients with metastatic breast cancer.\textsuperscript{8,9} Elevated levels of circulating tumor cells (defined as ≥5 cells per 7.5 ml of blood) have been associated with a worse prognosis.\textsuperscript{8,10}

Circulating DNA fragments carrying tumor-specific sequence alterations (circulating tumor DNA) are found in the cell-free fraction of blood, representing a variable and generally small fraction of the total circulating DNA.\textsuperscript{11,12} Advances in sequencing technologies have enabled the rapid identification of somatic genomic alterations in individual tumors, and these can be used to design personalized assays for the monitoring of circulating tumor DNA. Studies have shown the feasibility of using circulating tumor DNA to monitor tumor dynamics in a limited number of patients with various solid cancers, but few cases of breast cancer have been analyzed.\textsuperscript{13-20} Here, we provide a direct comparison between circulating tumor DNA and other circulating biomarkers (CA 15-3 and circulating tumor cells) and medical imaging, the current standard of care, for the noninvasive monitoring of metastatic breast cancer.

### Methods

#### Patients and Sample Collection

We carried out a prospective, single-center study to compare the sensitivity of measuring circulating tumor DNA, CA 15-3, and circulating tumor cells for monitoring tumor burden in patients with metastatic breast cancer (see the Supplementary Appendix, available with the full text of this article at NEJM.org). The study was approved by the local institutional research ethics committee.

Eligible patients were women with metastatic breast cancer currently undergoing active treatment. A total of 52 women were recruited, and 30 had genomic alterations suitable for monitoring. All women provided written informed consent. Serial blood samples (30 ml each) were collected between April 2010 and April 2012 at intervals of 3 or more weeks. Computed tomography (CT) was performed and reviewed in a blinded fashion to document response to treatment according to the Response Evaluation Criteria in Solid Tumors (RECIST), version 1.1.\textsuperscript{21} All reagents and equipment used in the study were purchased.

#### Identification of Somatic Genomic Alterations

Sequencing was performed on DNA from breast-cancer specimens and matched normal tissue specimens, with the use of one or both of two methods: tagged-amplicon deep sequencing\textsuperscript{22} for \textit{PIK3CA} (encoding the phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha protein) and \textit{TP53} (encoding tumor protein p53) or paired-end whole-genome sequencing (see the Supplementary Appendix). Tagged-amplicon deep sequencing was done by means of the Fluidigm Access Array and sequencing on the Illumina GAIIx or HiSeq instruments. Paired-end sequencing was done with the use of the Illumina HiSeq2000 instrument. Candidate mutations and structural variants were validated and confirmed to be somatic with the use of Sanger sequencing.

#### Isolation and Quantification of Circulating Tumor DNA

Blood samples that were collected in EDTA tubes were processed within 1 hour after collection and were centrifuged to separate the plasma from the peripheral-blood cells. DNA was extracted from
aliquots (2 ml) of plasma with the use of the QIAamp circulating nucleic acid kit (Qiagen). To measure the DNA carrying specific somatic genomic alterations in plasma, we carried out a microfluidic digital polymerase-chain-reaction (PCR) assay\textsuperscript{17,23-25} (using the Fluidigm BioMark system) or direct plasma sequencing by means of tagged-amplicon deep sequencing\textsuperscript{22} (using the Fluidigm Access Array and sequencing on the Illumina HiSeq2500 instrument) (see the Supplementary Appendix).

**Assay of CA 15-3 and Circulating Tumor Cells**

We measured levels of CA 15-3 in aliquots (50 μl) of plasma by means of the ADVIA Centaur immunoassay system (Siemens Healthcare). Blood samples were collected in CellSave Preservative Tubes (Veridex) and were processed within 96 hours for the enumeration of circulating tumor cells with the use of the CellSearch System (Veridex). The counting of circulating tumor cells was performed in a manner blinded to the results of CT and assessments of CA 15-3 or circulating tumor DNA.

**Statistical Analysis**

To estimate the sensitivity of each of the circulating biomarkers, we used a modified bootstrapping method.\textsuperscript{26} We randomly sampled the complete data set to obtain a new data set containing only one time point for each patient. This random sampling was repeated 1000 times to obtain 1000 data sets, each containing independent observations. For each data set, we calculated the sensitivity of each biomarker. The median sensitivity for each biomarker and the median difference in sensitivity between two biomarkers — circulating tumor DNA versus either CA 15-3 or circulating tumor cells — was then calculated across the 1000 data sets. The percentile method was used to obtain 95% confidence intervals.

Survival analysis was performed by fitting a different Cox regression model for each of the three variables of interest: circulating tumor DNA, circulating tumor cells, and CA 15-3. Each model was constructed with the use of the counting process notation (start, end, event),\textsuperscript{27} such that for each time period, the date of the visit was taken as the start, and the date before the next visit (or the date of last follow-up) was considered the end. The predictors were modeled as time-dependent covariates that use splines to account for nonlinear relationships. Estimated survival curves were produced for different values of the covariates at the first visit. Wald statistic P values were reported for each model, and relative hazard plots were computed for each covariate, showing the linear predictor relative to the mean value of the covariate (for details, see the Supplementary Appendix).

**Results**

**Identification of Somatic Genomic Alterations**

Clinical details, results of CT imaging, and serial whole-blood samples were collected prospectively from 52 women undergoing therapy for metastatic breast cancer (Fig. 1, and Table S1 in the Supplementary Appendix). DNA extracted from archival-tumor tissue samples was analyzed to identify somatic genomic alterations, with the use of two approaches. First, we used targeted deep sequencing to screen for point mutations in \textit{PIK3CA} and \textit{TP53},\textsuperscript{28} which we identified in 25 of the 52 patients (Table S2 in the Supplementary Appendix). Second, we used whole-genome paired-end sequencing of tumor-tissue specimens and matched normal-tissue specimens in 9 of the 52 patients. We identified somatic structural variants\textsuperscript{29} in 8 patients (Table S3 in the Supplementary Appendix), including 5 in whom no mutations were previously identified in \textit{PIK3CA} or \textit{TP53}, bringing the total number of patients with identified genomic alterations to 30 of 52 women (Fig. 1, and Fig. S1 in the Supplementary Appendix). In 3 patients, both mutations and structural variants were identified, enabling us to compare and contrast the use of point mutations\textsuperscript{13} and structural variants\textsuperscript{14,15} for serial monitoring of circulating tumor DNA. For 1 patient, we used whole-genome paired-end sequencing to identify multiple somatic mutations, enabling us to monitor multiple mutations in parallel in circulating tumor DNA (Table S2 in the Supplementary Appendix).

**Quantification of Circulating Tumor DNA in Plasma**

In the 30 women with somatic mutations or structural variants, circulating tumor DNA was quantified in a total of 141 serial plasma samples...
by means of either digital PCR assay or tagged-amplicon deep sequencing.

Digital PCR assay was performed in 97 plasma samples from 19 of the 30 patients to track both somatic mutations and structural variants. The sensitivity of digital PCR assay allowed for the detection of a mutant allele fraction of 0.1% or more (one mutant molecule in a background of 1000 wild-type molecules) (Fig. S2 in the Supplementary Appendix). Circulating tumor DNA was detected in 18 of the 19 women and in 80 of the 97 plasma samples (82%) analyzed.

As a high-throughput alternative to digital PCR assay, the remaining 44 plasma samples from the remaining 11 patients were analyzed with the use of tagged-amplicon deep sequencing. The sensitivity of tagged-amplicon deep sequencing allowed for the detection of a mutant allele fraction of 0.14% or more with a confidence margin of 0.95. Using this approach, circulating tumor DNA was identified in all 11 patients and in 35 of the 44 plasma samples (80%) analyzed.

In a subset of plasma samples in which circulating tumor DNA was analyzed by both techniques, quantification of mutant allele fraction by means of either tagged-amplicon deep sequencing or digital PCR assay showed excellent agreement (Fig. S3 in the Supplementary Appendix). Taken together, circulating tumor DNA was detected in 29 of the 30 women (97%) and in 115 of the 141 plasma samples (82%). The median quantity of circulating tumor DNA across all samples was 150 amplifiable copies per milliliter of plasma (interquartile range, 9 to 720) (Table S4 in the Supplementary Appendix). The median mutant allele fraction was 4% (interquar-
tile range, 1 to 14). The 1 patient in whom circulating tumor DNA was not detected (Patient 12) had a low burden of metastatic disease (small-volume mediastinal lymphadenopathy) and no evidence of disease progression during the study. Overall, levels of total plasma DNA were measured in parallel and had limited informative content (Fig. S4 in the Supplementary Appendix).

**CONCURRENT MONITORING OF MULTIPLE SOMATIC GENOMIC ALTERATIONS IN PLASMA**

Plasma levels of either mutations or structural variants identified in the tumor tissue of the same patient (Fig. SIC in the Supplementary Appendix) showed a similar dynamic pattern (Fig. 2A, and Table S4 in the Supplementary Appendix). This confirmed the utility and comparability of both
approaches. In women with tumors in which the genomic location of the structural variants overlapped with an amplified locus, such alterations were detected in the plasma at higher concentrations, confirming that the assay of circulating tumor DNA is quantitative (Fig. 2A, and Fig. S1B and Table S5 in the Supplementary Appendix).

When multiple mutations were identified in tumor-tissue samples (Fig. S1C in the Supplementary Appendix), they generally showed similar dynamic patterns in plasma (Fig. 2B, and Table S4 in the Supplementary Appendix). However, in some cases, we also observed evidence of clonal heterogeneity, whereby certain mutations dominated in the plasma (Fig. 2C, and Table S4 in the Supplementary Appendix). Tagged-amplicon deep sequencing also identified mutations in plasma that were not detected in archival-tumor DNA (Fig. S1C in the Supplementary Appendix). These mutations showed diverging patterns over the course of disease progression and treatment (Fig. 2D, and Table S4 in the Supplementary Appendix), as compared with the mutations identified in the tumor, suggesting that they originated from different subclones.

SENSITIVITY OF CIRCULATING TUMOR DNA, CA 15-3, AND CIRCULATING TUMOR CELLS

Data comparing CA 15-3 values and circulating tumor DNA levels were available across 114 serial time points for 27 patients (Fig. 3A, and Table S4 in the Supplementary Appendix). CA 15-3 levels were elevated (>32.4 U per milliliter) at one or more time points in 21 of the 27 women (78%) and in 71 of the 114 samples (62%). In contrast, circulating tumor DNA was detected in 26 of 27 women (96%) and in 94 of 114 samples (82%). Of the 43 samples without elevated CA 15-3 levels, 27 (63%) had measurable levels of circulating tumor DNA. Using a modified bootstrapping method, we showed improved sensitivity of circulating tumor DNA as compared with CA 15-3 (85% vs. 59%), with a median difference in sensitivity of 26% (95% confidence interval [CI], 11 to 37; P<0.002).

Circulating tumor cells were quantified by means of the CellSearch System at 126 time points for all 30 women (Fig. 3B, and Table S4 in the Supplementary Appendix). Circulating tumor cells (≥1 cell per 7.5 ml of blood) were detected at one or more time points in 26 of the 30 women (87%), and elevated circulating tumor cells (≥5 cells per 7.5 ml of blood) were identified in 18 of the 30 women (60%). Of the 126 samples, 50 (40%) had no detected circulating tumor cells, and 76 (60%) had 1 or more cells per 7.5 ml, of which 46 (37% of all 126 samples) had 5 or more cells per 7.5 ml. In contrast, circulating tumor DNA was detected in 29 of the 30 women (97%) and at 106 of 126 time points (84%). In the 50 samples in which no circulating tumor cells were detected, 33 (66%) had measurable levels of circulating tumor DNA. According to the modified bootstrapping method, circulating tumor DNA had sensitivity superior to that of circulating tumor cells (90% vs. 67%), with a median difference in sensitivity of 27% (95% CI, 13 to 37; P<0.002). At the median, the number of amplifiable copies of circulating tumor DNA was 133 times the number of circulating tumor cells and had a greater dynamic range (Fig. 3B).

CT AND CIRCULATING BIOMARKERS FOR TUMOR MONITORING

We compared the performance of circulating biomarkers with the performance of CT in 20 patients with measurable disease (as defined by RECIST21) and for whom circulating biomarker data were available at 3 or more time points over a period of more than 100 days of follow-up (Fig. S5 in the Supplementary Appendix). Circulating tumor DNA was detected and showed serial changes in 19 of 20 women (95%) with fluctuations in circulating tumor DNA generally correlating with treatment responses seen on imaging (Fig. 4A, and Fig. S5 in the Supplementary Appendix). Similar findings were noted for women with 5 or more circulating tumor cells per 7.5 ml of blood (10 of 20 patients [50%]) in which serial changes in circulating tumor cell counts were evident and corresponded with responses ascertained on CT (Fig. 4A). However, in the remaining 10 women with a maximal count of circulating tumor cells of fewer than 5 cells per 7.5 ml of blood, the number of circulating tumor cells was uninformative (Fig. 4B and 4C, and Fig. S5 in the Supplementary Appendix).

Similar to the findings regarding circulating tumor cells was the finding that women with high levels of CA 15-3 had fluctuations corresponding to responses on imaging but with a smaller dynamic range (Fig. 4A and 4B, and Fig.
In patients with levels of CA 15-3 of 50 U or less per milliliter (8 of 19 patients [42%]), no consistent sequential changes in CA 15-3 levels were seen (Fig. 4C, and Fig. S5 in the Supplementary Appendix). Progressive disease was documented on CT (as defined by RECIST) in 19 of 20 women during the follow-up period; CA 15-3 data were available for 18 of these women (95%) (Fig. S5 in the Supplementary Appendix). Increases in circulating tumor DNA levels reflected progressive disease in 17 of the 19 women (89%). In these women, on average, circulating tumor DNA levels increased by a factor of 505 (range, 2 to 4457) from the nadir before the establishment of progressive disease.

---

**Figure 3.** Comparison of Circulating Tumor DNA, CA 15-3, and Circulating Tumor Cells as Blood-Based Biomarkers.

Panel A shows comparisons of CA 15-3 levels (U per milliliter of plasma) and circulating tumor DNA (ctDNA) levels (amplifiable copies per milliliter of plasma) across the maximal value analyzed for individual patients and across all samples analyzed for all patients. The green horizontal dashed line indicates the CA 15-3 threshold of 32.4 U per milliliter. The Spearman correlation coefficient (r) between CA 15-3 levels and ctDNA levels across all time points was 0.36 (P<0.001). Panel B shows comparisons of circulating tumor cell (CTC) numbers (per 7.5 ml of whole blood) and ctDNA numbers (amplifiable copies per 3.75 ml of plasma) across the maximal value analyzed for individual patients and across all samples analyzed for all patients. Copy numbers of ctDNA were adjusted for direct comparison to the numbers of circulating tumor cells from an equivalent volume of whole blood (7.5 ml). The purple dashed line indicates the CTC threshold of 1 cell per 7.5 ml of blood, and the orange dashed line indicates the CTC threshold of 5 cells per 7.5 ml of blood. The Spearman correlation coefficient (r) between quantified ctDNA levels and numbers of CTCs across all time points was 0.61 (P<0.001). ND denotes not detected.
Tumor cells increased in 7 of the 19 women (37%), and CA 15-3 levels increased in 9 of 18 women (50%) (Fig. S5 in the Supplementary Appendix). In 10 of the 19 patients (53%), levels of circulating tumor DNA increased at one or more consecutive time points, on average 5 months (range, 2 to 9) before the establishment of progressive disease by means of imaging (Fig. 4D, and Fig. S5 in the Supplementary Appendix). In 2 women (Patients 9 and 22), increasing levels of circulating tumor DNA did not reflect the presence of progressive disease as assessed on CT (a detailed description...
of these patients is provided in Fig. S5 in the Supplementary Appendix).

**PROGNOSTIC USE OF CIRCULATING BIOMARKERS**

Finally, we compared the circulating biomarkers with respect to prognostic use. Using a Cox proportional-hazards model in which circulating tumor DNA was treated as a continuous time-dependent variable, we found that increasing levels of circulating tumor DNA were associated with inferior overall survival (P<0.001) (Fig. 4E). Circulating tumor cells were also found to have prognostic significance (P=0.03) (Fig. S6A in the Supplementary Appendix). In contrast, CA 15-3 was not found to be prognostic in this series of patients (Fig. S6B in the Supplementary Appendix). Increasing numbers of circulating tumor cells and increasing levels of circulating tumor DNA were associated with an increased hazard (Fig. 4F), indicating that absolute levels of each is informative in guiding prognosis.

**DISCUSSION**

In the detection of metastatic breast cancer, circulating tumor DNA shows superior sensitivity to that of other circulating biomarkers and has a greater dynamic range that correlates with changes in tumor burden. Circulating tumor DNA often provides the earliest measure of treatment response, as has been supported by recent analyses of circulating tumor DNA in other solid cancers.20,32

The monitoring of circulating tumor DNA levels requires the identification of somatic alterations in individual patients. Future developments will reduce the cost of whole-genome paired-end sequencing, and targeted sequencing can be readily expanded to include other genes, in addition to PIK3CA and TP53, known to be recurrently mutated in breast cancer.33-35 Here we have demonstrated the use of two strategies to quantify circulating tumor DNA: digital PCR assay and targeted deep sequencing. Digital PCR assay provides high accuracy and sensitivity but requires the design of personalized assays, an expensive and rate-limiting step. Targeted deep sequencing of plasma DNA provides a cost-effective alternative for high-throughput analysis and may overcome limitations of initial tumor-tissue assessment by virtue of allowing for the direct identification of mutations in plasma.22 However, our findings on circulating tumor DNA are not limited to these molecular platforms. Other methods for the identification of somatic mutations (such as exome sequencing33) or for the quantification of circulating tumor DNA (e.g., BEAMing [beads, emulsions, amplification, and magnetics] or Safe-SeqS [Safe-Sequencing System]39) may be applied with even greater sensitivity. Recent studies have also shown the feasibility of performing genomewide analysis of tumor-associated copy-number changes and mutations in plasma.37-39

Our expanding knowledge of the genetic mechanisms underpinning breast cancer now provides a framework to better stratify patients.30,33-35,40,41 The analysis of circulating tumor DNA represents a unique opportunity to integrate this knowledge into the clinical arena. Although the acquisition of tumor-tissue specimens will continue to be important, the use of biopsy specimens is limited, since such material may...
not capture tumor heterogeneity; in addition, repeated biopsy is impractical. Circulating tumor DNA represents a “liquid biopsy” alternative, allowing for sensitive and specific serial sampling to be performed during the course of treatment.
